## Chapter 1

# The HILECOP model-to-text transformation

- Motivate the interest of the transformation in the introduction. Why the models are not hand-coded in VHDL directly? Because graphics help the design and communication, automatic generation because places and transitions interconnections to complex...
- Principles of SITPNs implementation in VHDL: place pivot, keep place and transition design as simple as possible, interconnections via Boolean signals only

The aim of this chapter is to present in details the HILECOP model-to-text transformation that we propose to verify as semantic preserving. The chapter is structured as follows. First, we present, in Section 1.2, a literature review of the works pertaining to transformation functions in the context of formal verification. The literature review focuses on the expression of transformation functions and on their implementation. In Section 1.3, we detail the HILECOP transformation function in the form of an algorithm. Finally, in Section 1.4, we describe the Coq implementation of the algorithm.

## 1.1 Informal presentation of the HILECOP transformation

Here, we give an overview of the HILECOP transformation function. The goal is to give to the reader the means to appreciate the difference and the similarities between the HILECOP transformation and the other transformations presented in the literature review of Section 1.2. Then, Section 1.3 will enter the details of the transformation by presenting the transformation algorithm.

The HILECOP model-to-text transformation function takes an SITPN model as an input; then, it generates a top-level  $\mathcal{H}$ -VHDL design out of the input model. We will illustrate the HILECOP model-to-text transformation on the input SITPN model presented in Figure 1.1.

FIGURE 1.1: Transformation of an input SITPN model into a top-level  $\mathcal{H}$ -VHDL design. The input model is composed of two places,  $p_0$  and  $p_1$ , and two transitions,  $t_0$  and  $t_1$ . Transition  $t_0$  is associated with the time interval  $[1, 3]$  and the condition  $c_0$ . Transition  $t_1$  is associated with condition  $c_1$ , and its firing triggers the execution of function  $f_0$ . Action  $a_0$  is activated when place  $p_0$  is marked, and action  $a_1$  is activated when place  $p_1$  is marked.

The generated top-level design implements the structure of the input SITPN. As a first step, the transformation generates for each place of the input SITPN a component instance of the place design, and for each transition of the input SITPN a component instance of the transition design. These subcomponents constitute the main part of the  $\mathcal{H}$ -VHDL top-level design's behavior. Figure 1.2 shows the content of the behavior of the top-level design after this first generation step. In addition to the generation of PCIs and TCIs, all constant values are produced in the generic map and the input port map of component instances. The constant values pertain to all the information related to the structure of the input SITPN. The generic map of TCIs receive the number of conditions, the type of time interval, and the maximal value for the time counter associated with their corresponding transitions. The generic map of PCIs receive the number of input arcs, the number of output arcs, and the maximal marking associated with their corresponding places. The maximal marking associated with each place of the input SITPN is an information passed as a parameter to the transformation function. This information comes from the analysis of the input SITPN pertaining to the boundedness of the input model. This analysis takes place before the transformation into a  $\mathcal{H}$ -VHDL design in the proceeding of the HILECOP methodology. For now, a global maximal marking is passed as a parameter to the transformation function; therefore, all PCIs receive the same value for the `maximal_marking` generic constant in the first phase of the transformation. However, we can easily convert the global maximal marking into a function mapping the places of the input SITPN to a specific maximal marking value. Thus, each PCI would be associated with their own maximal marking value at the generation of their generic map. The input port map of

PCIs receive the weight and type of input arcs, and the weight of output arcs for each input and output arc of their corresponding places.

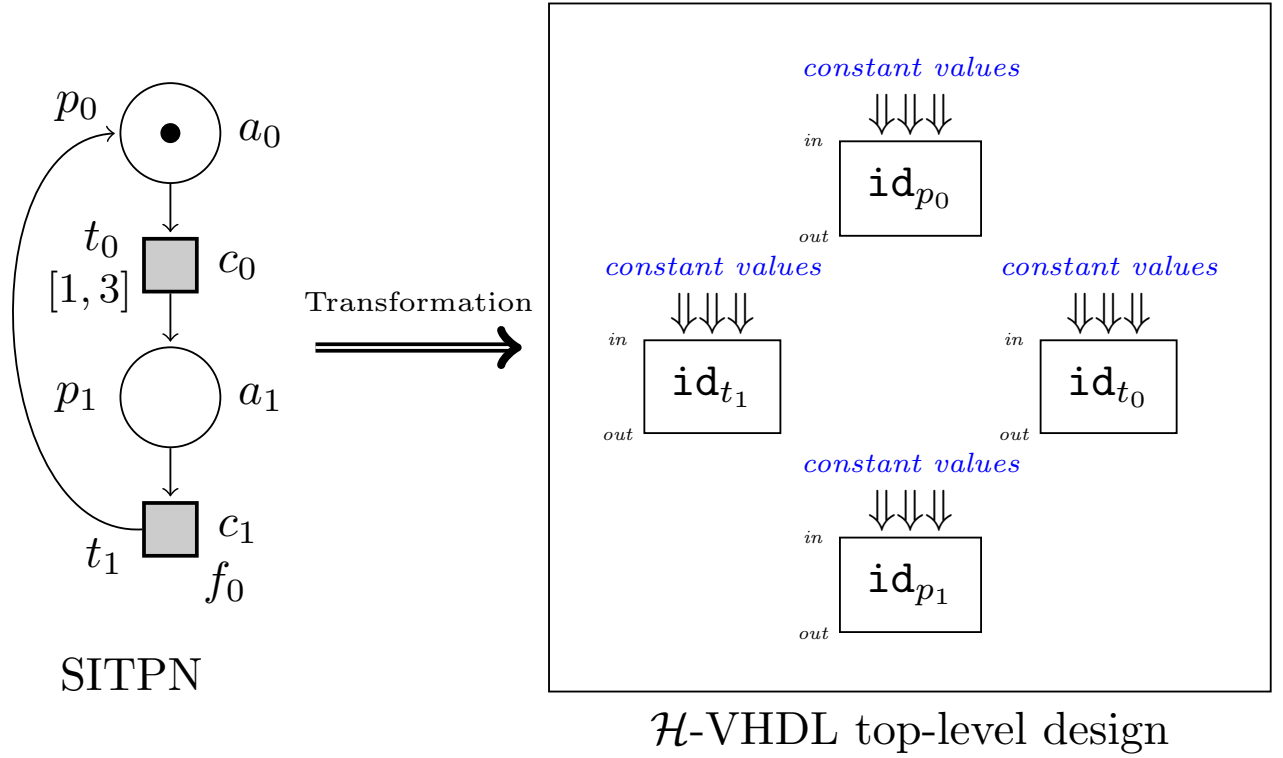

FIGURE 1.2: Generation of the place and transition component instances based on the set of places and transitions of the input SITPN. The PCI  $id_{p_0}$  implements the place  $p_0$ , TCI  $id_{t_0}$  the transition  $t_0$ ,...

After the generation of the PCIs, the TCIs, and of the constant parts of the generic and input port maps, the component instances are interconnected through their port interfaces. The PCIs and TCIs interact through their interfaces to exchange informations. Figure 1.3 illustrates the behavior of the top-level design after the interconnection of PCIs and TCIs. For instance, a PCI, implementing a given place  $p$ , informs its output TCIS (i.e. the TCIs implementing the output transitions of  $p$ ) that its current marking enables them. The marking of a PCI is represented by the value of its internal signal `s_marking`. The PCI is the only one to have access to the current value of its internal signals. Thus, a PCI must communicate to its output TCIs about their sensitization status. To perform this exchange of information, the transformation generates an internal signal to connect the subelements of the `output_arcs_valid` output port<sup>1</sup>, where `output_arcs_valid` is defined in the output port map of the PCI. Each subelement of the `output_arcs_valid` port is connected to one subelement of the `input_arcs_valid` input port, where `input_arcs_valid` is defined in the input port map of TCIS. Likewise, a TCI informs its input and output PCIs about its firing status. The transformation generates an internal signal to connect the `fired` output port, defined in the output port map of the TCI, to the

<sup>1</sup>The `output_arcs_valid` output port is a composite port, i.e. of the *array* type.

input\_transitions\_fired and output\_transitions\_fired input ports, defined in the input port map of the input and output PCIS. Through the execution of the internal behavior of each PCI and TCI, and, through the interconnection of component instances, the transformation aims at generating a design's behavior that, by its very structure, carries the rules of the SITPN semantics and conforms to the input SITPN model. To reduce the size of circuits after the synthesis on an FPGA card, PCIs and TCIs only communicate with Boolean signals through their interfaces.

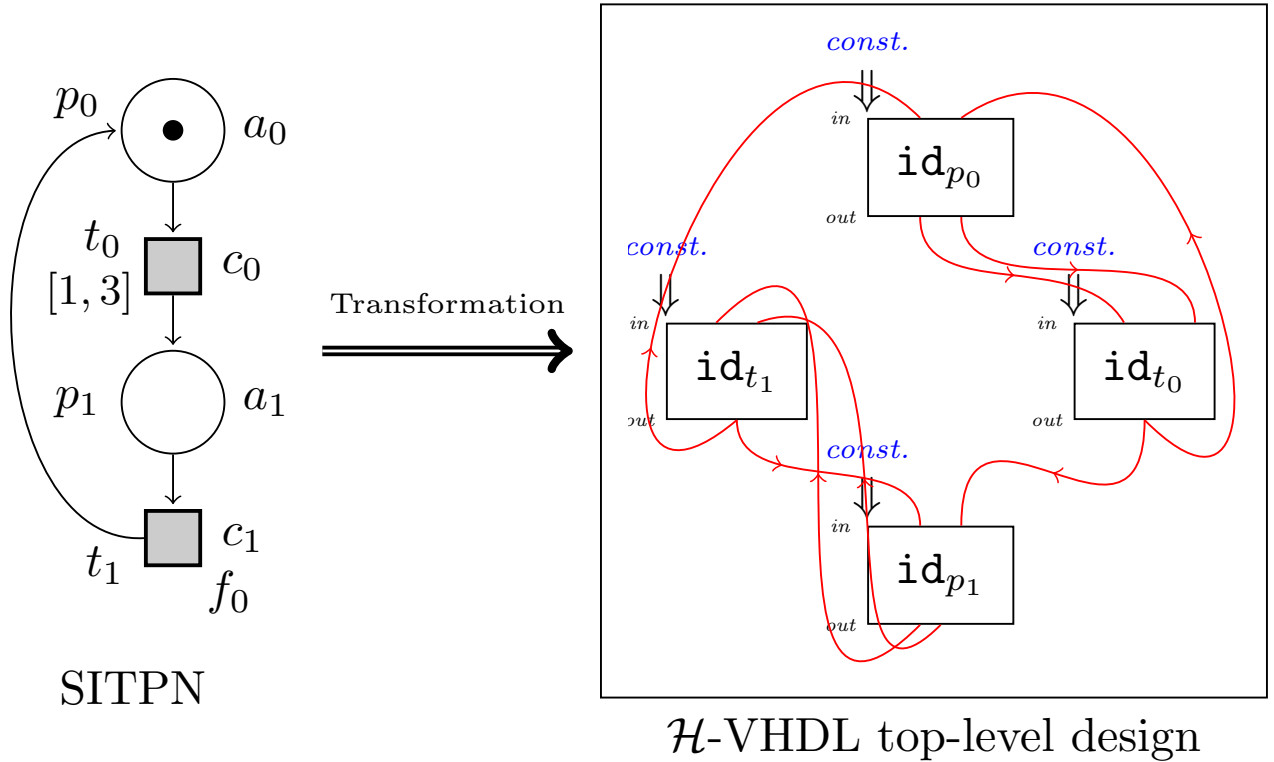

FIGURE 1.3: Generation of the interconnections between the place and transition component instances. In red, the internal signals interconnecting the PCIs and the TCIs. These signals are generated by the transformation. The arrows indicate the sense of propagation of the information. In blue, the constant values produced at the previous transformation step.

The last part of the transformation deals with the interpretation elements of the input SITPN, i.e. the conditions, the actions and the functions. Each condition of the input SITPN leads to the declaration of a Boolean input port in the port clause of the top-level design. Then, in the design's behavior, each input port is connected to the input\_conditions input port of TCIs. The interconnection of an input port of the top-level design to the input\_conditions input port of a TCI reflects an existing association between a transition and a condition of the input SITPN model. For each action and function of the input SITPN, the transformation generates a Boolean output port, a.k.a. an *action* or a *function* port. At runtime, the value of these output ports represent the activation or execution status of the corresponding actions and functions. To determine the value of the action and function ports, the transformation generates the

action and the function) process. The action process is a synchronous process responding to the falling edge of the clock signal. At the occurrence of the falling edge of the clock signal, the action process sets the value of the *action* ports computed from the values of the marked output ports. The marked output port belongs to the output port map of PCIs. Through the Boolean marked output port, the PCIs inform the outside about their marking status, i.e. if they possess at least one token or not. The function process is a synchronous process responding to the rising edge of the clock signal. At the occurrence of the rising edge of the clock signal, the function process sets the value of the *function* ports computed from the values of the fired output ports. The fired output port belongs to the output port map of TCIs. Through the Boolean fired output port, the TCIs inform the outside about their firing status, i.e. if they are fired or not. Figure gives the top-level  $\mathcal{H}$ -VHDL design at the end of the transformation.

FIGURE 1.4: Generation of the input and output ports, and of the action and the function process in the  $\mathcal{H}$ -VHDL top-level design. The *primary* input port  $id_{c_1}$  (resp.  $id_{c_0}$ ) implements the condition  $c_1$  (resp.  $c_0$ ). In **green**, the internal signals, generated by the transformation, connecting the input ports of the top-level design to the input\_conditions input port of TCIs. The  $id_{a_0}$  and  $id_{a_1}$  output ports reflect the activation status of actions  $a_0$  and  $a_1$ . The  $id_{f_0}$  output port reflect the activation status of function  $f_0$ . In **orange**, the internal signals, generated by the transformation, connecting the marked and fired output ports of PCIs and TCIs to the action and function processes. In **purple**, the representation of the assignment performed by the action and function processes the action and function ports.

## 1.2 Expressing transformation functions

In this section, we present our literature review pertaining to transformation functions in the context of formal verification. Here, a transformation function is understood as any kind of mapping from a source representation to a target representation, where the source and target representations possess a behavior of their own (i.e, they are executable). Especially, we are interested in two things:

1. Is there a proper way to build a transformation function? Do standards exist to do this depending on the application domain? How can we build a modular, extensible transformation function? How can we build a transformation function that will ease the proof of semantic preservation?
2. In the context of formal verification, how are expressed the semantic preservation theorems? Are there usual proof strategies?

Here, the goal is to inspire ourselves with the work of the literature, and to see how far the correspondence holds between our specific case of transformation, and other cases of transformations. The results of the literature review are presented in two parts. The two parts have been prepared based on the same material. The first part will be focusing on the expression of the transformation functions in the literature, and the second part will be focusing on the proof that these transformations are semantic preserving ones.

The material we used for the literature review is divided in three categories. Each category covers a specific case of transformation function, always taken in the context of formal verification. Thus, the three categories are:

- Compilers for generic programming languages
- Compilers for hardware description languages
- Model-to-model and model-to-text transformations

### 1.2.1 Building transformation functions

As the authors state in [15], “Although theoretically possible, verifying a compiler that is not designed for verification would be a prohibitive amount of work in practice.” The question is to know how to design such a compiler? How to anticipate the fact that we will have to prove that the compiler is semantic preserving? We open these to the more general context of transformation functions that map a source representation to target one.

#### Compilers for generic programming languages

In the context of formally verified compilers for generic programming languages, translation from a source program to a target program is mostly straight forward. While descending recursively through the AST of the input program, each construct of the source language is mapped to one or many constructs of the target language. Figure 1.5 gives an example of the translation

from Java program expressions to Java bytecode expressions, set in the context of a compiler for Java programs written within the Isabelle/HOL theorem prover [14]. Here, the mapping between source and target constructs is clearly defined.

```

mkExpr jmb (NewC c) = [New c]
mkExpr jmb (Cast c e) = mkExpr jmb e @ [Checkcast c]
mkExpr jmb (Lit val) = [LitPush val]
mkExpr jmb (BinOp bo e1 e2) = mkExpr jmb e1 @ mkExpr jmb e2 @
  (case bo of
    Eq => [Ifcmpeq 3, LitPush(Bool False), Goto 2, LitPush(Bool True)]
  | Add => [IAdd])
mkExpr jmb (LAcc vn) = [Load (index jmb vn)]
mkExpr jmb (vn := e) = mkExpr jmb e @ [Dup , Store (index jmb vn)]
mkExpr jmb (cne..fn) = mkExpr jmb e @ [Getfield fn cn]
mkExpr jmb (FAss cn e1 fn e2) =
  mkExpr jmb e1 @ mkExpr jmb e2 @ [Dup.x1 , Putfield fn cn]
mkExpr jmb (Call cn e1 mn X ps) =
  mkExpr jmb e1 @ mkExprs jmb ps @ [Invoke cn mn X]
mkExprs jmb [] = []
mkExprs jmb (e#es) = mkExpr jmb e @ mkExprs jmb es

```

FIGURE 1.5: Translation from Java expressions to Java bytecode expressions

In the works pertaining to the well-known CompCertproject [11, 2], the many passes building the compiler from C programs to assembly languages are also clearly mapping each construct of source program to target program constructs. This is all the more natural, since the languages like Coq, Isabelle, HOLand other interactive theorem provers permit to perform pattern matching on the abstract syntax tree of the source programs.

The cases of optimizing compilers, like [11] and [16], show that to avoid to write too complex functions when passing from source to target program, that would too difficult to handle during the semantic preservation proof, the compilation is decomposed into many passes. No more than 12 passes for the CakeML compiler, and up to 7 passes for CompCert. This is a way to keep translation functions simple in order to ease reasoning afterwards. Indeed, the more the gap is important between the source representation and the target one, the more the translation function will be complex.

Another point that is noticeable is the expression of translation function is the necessity to keep a binding between source and target representations. For instance, in CompCert, when passing from transformed C programs to an RTL representation (based on registers and control flow graphs), a binding function  $\gamma$  links the variables found in C programs to the registers generated in the RTL representation. The binding is important for the translation (replacing variables by their corresponding registers in the RTL code), and for the proof when values from the source program will be compared to values in the target program. This is a thing that should be anticipated when writing a translation function, i.e what is the correspondence between source and target elements.

In [11], and [7], compilers are written within the Coq proof assistant. Compilers are expressed using the state-and-error monad, thus mimicking the traits of imperative languages into a functional programming language setting.

### Compilers for hardware description languages

The other category of compilers that we are interested in are compilers for hardware description languages (HDL). The HILECOP methodology's goal is the design of hardware circuits. For that reason, we are interested in studying the case of compilers for HDLs. However, one should notice that compiling a HDL program into a lower level representation is one level of abstraction down compared to the transformation we propose to verify. Indeed, it corresponds to step 3 in the HILECOP methodology, i.e the translation from VHDL to RTL representation.

In the context of formal verification applied to HDLs compilers, only a few works describe the specificities of their translation function.

In [5], the authors describe the definition of the language FeSi (a refinement of the BlueSpec language, a specification language for hardware circuit behaviors), and its embedding in Coq. The authors present the syntax and semantics of the FeSi and of the RTL language which is the target language of the compiler. FeSi programs are composed of simple expressions, and actions permitting to read or write from different types of memory (registers). Therefore, the abstract syntax is divided into the definition of expressions and the definition of actions, i.e: control flow instructions and operations on memory. The RTL language is composed of expressions and write operations to registers. The authors are more interested in proving that a FeSi specification is well-implemented by a given Coq program, than giving the details of the translation from FeSi to RTL. However, the translation seems straight-forward, and proceeds as usual by descending through the AST of FeSi programs.

In [3], the authors present a compiler for the language Koïka, which is also a simplification of the BlueSpec language. A Koïka program is composed of a list of rules; each rule describes actions that must be performed atomically. Actions are read and write operations on registers. A Koïka program is accompanied by a scheduler that specifies an execution order for the rules. The described compiler transforms Koïka programs into RTL descriptions of hardware circuits. The translation function builds an RTL circuit by descending recursively down the AST of rules. Each action is translated into a specific RTL representation which are afterwards composed together to get complex circuits. The translation becomes trickier when it comes to decide the composition of RTL circuits to respect the execution order prescribed by the scheduler.

In [4], the authors present the verification of a compiler toolchain from Lustre programs to an imperative language (Obc), and from Obc to Clight. The Clight target is the one defined in CompCert[11]. Lustre permits the definition of programs composed of nodes that are executed synchronously. Nodes treat input streams and yield output streams of values. A node body is composed of sequence of equations that determine the values of output streams based on the input. Obc programs are composed of class declarations. A class declaration has a vector of memory variables, a vector of instances of other classes, and method declarations. The translation turns each node of a Lustre program into a class of Obc having two methods: *reset*, for the initialization of the streams, and *step*, for the update of values resulting of a synchronous step.

In [12], the authors describe a compiler that transforms Verilog programs into netlists targeting certain FPGA models. Verilog programs are a lot like VHDL programs; they describe a hardware circuit behavior in terms of processes. A netlist is composed of registers, variables and a list of cells corresponding to combinational components. During the translation process,

the expressions of the Verilog programs are turned into netlist cells, and the composition of statements leads to the creation of complex circuits by means of cell composition.

### Model transformations

We are now presenting the works pertaining to model-to-model and model-to-text transformations in the context of formal verification. Because of the very nature of the transformation we propose to verify, i.e a model-to-text transformation in the HILECOP methodology, the following works are of particular interest to us. We will focus here on the manner to express transformations in the case of model-to-model and model-to-text transformations. Also, we tried to find articles related to model transformations involving Petri nets.

In [1], the authors observe that Model-Driven Engineering (MDE) is all about model transformation operations. They propose to set a formal context within the Coq proof assistant to verify that model transformations preserve the structure of the source models into the target models. To illustrate their methodology, they choose to transform UML state machine diagrams into Petri net models. The translation rules from source to target models are expressed within the setting of the OMG standard QVT language (Query/View/Transform). The QVT language offers a formal way to express model transformations, partly based on the Object Constraint Language (OCL). The translation rules maps the different kind of structures that can be found in UML state diagrams to specific structures of Petri nets. Even though the two models used as source and target of transformations are executable, the authors leverage the formal context provided by Coq to prove that the expressed transformations preserve certain structural properties.

In [6], the authors describe a process for model transformation where transformation rules are expressed with the Atlas Transformation Language (ATL). Transformation rules in ATL involve both declarative (OCL) and imperative (match rules) instructions. The authors show how the ATL rules can easily be translated into Coq relations. An example is given on the kind of model-to-model transformations that can be implemented that way. The example is a UML class diagram to relational database model transformation.

In [8], the authors explore the different ways to give a formal semantics to a Domain-Specific Language (DSL) in the context of MDE. Consequently, the DSL is expressed with a meta-model. An instantiation of this meta-model (a model) yields a DSL program. The authors specify a transformation from a DSL model to another executable model. While giving an operational semantics to the DSL models, the aim of the transformation is to be able to compare the execution of the target models with the execution of the source models. The authors illustrate their approach with a source DSL named xSPeM, a process description language, and the model domain is timed PNs. The translation is expressed through a structural mapping; i.e, each element of an xSPeM model is mapped to a particular PN: an activity is mapped to a subnet, a resource to a single place, connection from activity to resource through parameter is mapped to a connection of transitions and places in the resulting PN...

In [9], the authors address the problem of expressing model transformations by using transformation graphs. Precisely, the kind of transformation graphs that are used are called Triple Graph Grammar (TGG). A TGG is a triplet  $\langle s, c, t \rangle$  where the “correspondence model  $c$  explicitly stores correspondence relationships between source model  $s$  and target model  $t$ ”.

The work described in [10] is really close to our own verification task. The article describes how Coloured Petri Nets (CPNs, specifically LLVM-labelled Petri nets) are transformed into LLVM programs representing the state space (the graph of reachable markings) of these PNs. The aim is to enable an efficient model-checking of the CPNs. LLVM-labelled PNs are CPNs whose places, transitions and arcs have LLVM constructs for colour domains. Places are labelled with data types. Transitions are labelled with boolean expressions, that correspond to the guard of the transition. Arcs are labelled by multisets of expressions. A marking is a function that maps each place to a multiset of values belonging to the place's type. The authors define data structures (multisets, sets, markings,...) with interfaces, i.e sets of operations over structures, to represent the Petri nets in LLVM. They define interpretation functions that draw equivalences between Petri nets objects and LLVM data structures. The authors define two algorithms: `fire_t` and `succ_t` to compute the graph of reachable states. These are the functions that transform CPNs into concrete LLVM programs.

In [13], the author describe a transformation from UML state machine diagrams to Coloured Petri Nets (CPNs). The aim is to leverage the means of analysis provided by Petri nets to certify certain properties over UML state machine diagrams. The authors want to verify that the transformation preserve structural properties between source and target models. The transformation function does not use a standard setting as QVT or ATL, or transformation graphs. It is expressed as a specific function written in Isabelle/HOL.

In [17], the author present a transformation from Architecture Analysis and Design Language (AADL) models to Timed Abstract State Machines (TASMs). AADL is a language widely used in avionics to describe both hardware and software systems. AADL doesn't have a lot of tools to analyze and simulate the designed systems; therefore transforming AADL models into TASM enables the use of an important toolbox for analysis, and simulation. The transformation from AADL to TASMs are described with ATL rules.

### Discussions on how to build transformation functions in the context of semantic preservation

Transformation functions are mappings from a source representation to a target representation. The more the mapping from source to target is straight-forward the easier the comparison will be when proving that the transformation is semantic preserving. Thus, in [11, 16, 7] where complex case of optimizing compilers are presented, the compilation is split into many simple pass to ease the verification effort coming afterwards.

Also, while translating source programs, the compiler must often generate fresh constructs belonging to the target language (for instance, generating an fresh RTL register for each variable referenced in the source C program in [11]). The compiler must keep a binding, that is, a memory of the mapping between the elements of the source program and their mirror in the target program. This consideration is of interest in our case of transformation where the elements of SITPNs are also mirrored by elements in the generated  $\mathcal{H}$ -VHDL design.

It remains hard to establish a standard way to express a transformation function as it really depends of the form of the input and the output representation. Compilers for programming languages tend to be a lot more compositional than model transformations. Compositional meaning that the translation rules can be split into simple and independent cases of translation,

e.g translation of expressions, then translation of statements, then translation of function bodies, ... In the world of models, there exist some standard formalisms to express transformation rules (QVT, ATL, transformation graphs...). However, the complexity of the transformation rules depends on the richness of the elements composing the source model, and the distance to the concepts of the target model.

### 1.3 The transformation algorithm

**Definition 1** (SITPN-to- $\mathcal{H}$ -VHDL Design Binder). *Given a  $sitpn \in SITPN$  and a  $\mathcal{H}$ -VHDL design  $d \in design$ , a SITPN-to- $\mathcal{H}$ -VHDL design binder  $\gamma \in WM(sitpn, d)$  is a tuple  $\langle PMap, TMap, C_{id}, A_{id}, F_{id}, CMap, AMap, FMap \rangle$  where:*

- $sitpn = \langle P, T, pre, test, inhib, post, M_0, \succ, \mathcal{A}, \mathcal{C}, \mathcal{F}, \mathbb{A}, \mathbb{C}, \mathbb{F}, I_s \rangle$
- $d = design\ id_{ent}\ id_{arch}\ gens\ ports\ sigs\ behavior$
- $PMap \in P \rightarrow P_{id}$  where  $P_{id} = \{id \mid comp(id, "place", gm, ipm, opm) \in behavior\}$
- $TMap \in T \rightarrow T_{id}$  where  $T_{id} = \{id \mid comp(id, "transition", gm, ipm, opm) \in behavior\}$
- $C_{id} \subseteq \{id \mid (in, id, t) \in ports \wedge id \notin \{"clk", "rst"\}\}$
- $A_{id} \subseteq \{id \mid (out, id, t) \in ports\}$
- $F_{id} \subseteq \{id \mid (out, id, t) \in ports\}$
- $CMap \in \mathcal{C} \rightarrow C_{id}$
- $AMap \in \mathcal{A} \rightarrow A_{id}$
- $FMap \in \mathcal{F} \rightarrow F_{id}$

Afterwards, for a given binder  $\gamma$  and an element of an SITPN structure  $e \in P \sqcup T \sqcup \mathcal{C} \sqcup \mathcal{A} \sqcup \mathcal{F}$ , we write  $\gamma(e)$  where  $e$  is looked up in the appropriate function. For instance, for a given  $f \in \mathcal{F}$ ,  $\gamma(f)$  is a shorthand for  $FMap(f)$  where  $\gamma = \langle \dots, FMap \rangle$ .

### 1.4 Coq implementation of the HILECOP model-to-text transformation

→ talk about the state-and-error monad, the  $\gamma$  binder, the use of generic list functions (fold, map, filter, iter...)

CONCLUSION OF THE CHAPTER: Our transformation function is not really expressible in a compositional way as P and T instances are bound together. It's a specific case of model-to-text transformation. However, as much as the comparison with other works of transformation verification holds, we have been trying to inspire ourselves from the literature to implement the HILECOP model-to-text transformation function in Coq.
